Wave-Style Token Machines and Quantum Lambda Calculi

Ugo Dal Lago
Università di Bologna, Italy & INRIA

Margherita Zorzi
Università di Verona, Italy

Particle-style token machines are a way to interpret proofs and programs, when the latter are written following the principles of linear logic. In this paper, we show that token machines also make sense when the programs at hand are those of a simple quantum $\lambda$-calculus with implicit qubits. This, however, requires generalising the concept of a token machine to one in which more than one particle travel around the term at the same time. The presence of multiple tokens is intimately related to entanglement and allows us to give a simple operational semantics to the calculus, coherently with the principles of quantum computation.

1 Introduction

One of the strongest trends in computer science is the (relatively recent) interest in exploiting new computing paradigms which go beyond the usual, classical one. Among these paradigms, quantum computing plays an important role. In particular, the quantum paradigm is having a deep impact on the notion of a computationally (in)tractable problem [18].

Even if quantum computing has catalysed the interest of a quite large scientific community, several theoretical aspects are still unexplored. As an example, the definition of a robust theoretical framework for quantum programming is nowadays still a challenge. A number of (paradigmatic) calculi for quantum computing have been introduced in the last ten years. Among them, some functional calculi, typed and untyped, have been proposed [5, 6, 7, 16, 19, 22], but we are still at a stage where it is not clear whether one calculus could be considered canonical. Since quantum data have to undergo restrictions such as no-cloning and no-erasing, it is not surprising that in most of the cited quantum calculi the use of resources is controlled. Linear logic therefore provides an ideal framework for quantum data treatment, since weakening and contraction (to which linear logic gives a special status) precisely correspond to erasing and copying via the Curry-Howard correspondence. But linear logic also offers another tool which has not been widely exploited in the quantum setting: its mathematical model in terms of operator algebras, i.e. the Geometry of Interaction (GoI in the following). Indeed, the latter provides a dynamical interpretation and a semantic account of the cut-elimination procedure as a flow of information circulating into a net structure. This idea can be formulated both as an algebra of bounded operators on an infinite-dimensional Hilbert space [11] or as a token-based machine [12, 14]. On the one hand, the Hilbert space on top of which the first formulation of GoI is given is precisely the canonical state space of a quantum Turing machine [2]. On the other hand, the definition of a token machine provides a mathematically simpler setting, which has already found a role in this context [4, 13].

In this paper, we show that token machines are also a model of a linear quantum $\lambda$-calculus with implicit quantum bits (qubits), called QA and defined along the lines of van Tonder’s $\lambda_q$ [19]. This allows us to give an operational semantics to QA which renders the quantum nature of QA explicit: type derivations become quantum circuits on the set of gates occurring in the underlying $\lambda$-term. This frees us from the burden of having to define the operational semantics of quantum calculi in reduction style,
which is known to be technically challenging in a similar setting \cite{19}. On the other hand, the power of \( \beta \)-style axioms is retained in the form of an equational theory for which our operational semantics can be proved sound. Technically, the design of our token machine for \( QA \), called IAM\( QA \), is arguably more challenging than the one of classical token machines. Indeed, the principles of quantum computing, and the so-called entanglement in particular, force us to go towards wave-style machines, i.e., to machines where more than one particle can travel inside the program at the same time. Moreover, the possibly many tokens at hand are subject to synchronisation points, each one corresponding to unitary operators of arity greater than 1. This means that IAM\( QA \), in principle, could suffer from deadlocks, let alone the possibility of non-termination. We here prove that these pathological situations can never happen. In the present paper we also establish a soundness theorem: we state and prove that the semantics induced by the token machine IAM\( QA \) is sound with respect to \( QA \)'s equational theory, i.e. it is invariant with respect to term equivalence. The proof, which we only sketch and which can anyway be found in \cite{8}, is not trivial, since our notion of term has to deal with quantum superposition \cite{15} and is thus non-standard. Finally, it is mandatory to recall that, even if the possibility of observing quantum data is a useful and expressive programming tool, considering a measurement-free calculus is a theoretically well-founded choice, since measurements can always been postponed \cite{15}. Thus, this is not a limitation when one addresses computability issues.

The calculus \( QA \) and its token machine IAM\( QA \) are introduced in Section 2 and Section 3, respectively. Main results about IAM\( QA \) are in Section 4. An extended version of this paper with more details, proofs and a gentle introduction to quantum computing is available \cite{8}.

2 The Calculus \( QA \)

An essential property of quantum programs is that quantum data, i.e. quantum bits, should always be uniquely referenced. This restriction follows from the well-known no-cloning and no-erasing properties of quantum physics, which state that a quantum bit cannot in general be duplicated nor canceled \cite{15}. Syntactically, one captures this restriction by means of linearity: if every abstraction \( \lambda x.M \) is such that there is exactly one free occurrence of \( x \) in \( M \), then the substitution triggered by firing any redex is neither copying nor erasing and, as a consequence, coherent with the just stated principles. In this Section, we introduce a quantum linear \( \lambda \)-calculus in the style of van Tonder’s \( \lambda_q \) \cite{19} and give an equational theory for it. This is the main object of study of this paper, and is the calculus for which we will give a wave-style token machine in the coming sections.

2.1 The Language of Terms

Let us fix a finite set \( \mathcal{U} \) of unitary operators, each on a finite-dimensional Hilbert space \( \mathbb{C}^{n} \), where \( n \) can be arbitrary. To each such \( U \in \mathcal{U} \) we associate a symbol \( U \) and call \( n \) the arity of \( U \). The syntactic categories of patterns, bit constants, constants and terms are defined by the following grammar:

\[
\begin{align*}
P := & \ x \mid \langle x, y \rangle; \quad \text{patterns} \\
B := & \ |b\rangle_n; \quad \text{bit constants} \\
C := & \ B \mid U; \quad \text{constants} \\
M, N := & \ x \mid C \mid M \otimes N \mid MN \mid \lambda P.M. \quad \text{terms}
\end{align*}
\]
where $n$ ranges over $\mathbb{N}$, $b$ ranges over \{0, 1\}, and $x$ ranges over a denumerable, totally ordered set of variables $\mathcal{V}$. We always assume that the natural numbers occurring next to bits in any term $M$ are pairwise distinct. This condition, by the way, is preserved by substitution when the substituted variable occurs (free) exactly once. Whenever this does not cause ambiguity, we elide labels and simply write $|b\rangle$ for a bit constant. Notice that pairs are formed via the binary operator $\otimes$.

We will sometime write $|b_1 b_2 \ldots b_k\rangle$ for $|b_1\rangle \otimes |b_2\rangle \otimes \ldots \otimes |b_k\rangle$ (where $b_1, \ldots, b_n \in \{0, 1\}$). We work modulo variable renaming; in other words, terms are equivalence classes modulo $\alpha$-conversion. Substitution up to $\alpha$-equivalence is defined in the usual way. Observe that the terms of $\text{QL}$ are the ones of a $\lambda$-calculus with pairs (which are accessed by pattern-matching) endowed with constants for bits and unitary operators. We don’t consider measurements here, and discuss the possibility of extending the language of terms in sections 5 and 6.

### 2.2 Judgements and Typing Rules.

We want terms to be non-duplicable and non-erasable by construction and, as a consequence, we adopt a linear type discipline. Formally, the set of types is defined as follows

$$A ::= B \mid A \rightarrow B \mid A \otimes B,$$

where $B$ is the ground type of bits. We write $B^n$ for the $n$-fold tensor product $B \otimes \ldots \otimes B$. Judgements and environments are defined as follows:

- A **linear environment** $\Gamma$ is a (possibly empty) finite set of assignments in the form $x : A$. We impose that in a linear environment, each variable $x$ occurs at most once;
- If $\Gamma$ and $\Delta$ are two linear environments assigning types to distinct sets of variables, $\Gamma, \Delta$ denotes their union;
- A **judgement** is an expression $\Gamma \vdash M : A$, where $\Gamma$ is a linear environment, $M$ is a term, and $A$ is a type in $\text{QL}$.

**Typing rules** are in Figure 1. Observe that contexts are treated multiplicatively and, as a consequence, variables always appear exactly once in terms. In other words, a **strictly linear type discipline** is enforced.

**Example 1 (EPR States)** Consider the term $M_{\text{EPR}} = \lambda (x, y).\text{CNOT}(H x \otimes y)$. $M_{\text{EPR}}$ encodes the quantum circuit on two input qubits which has the ability to produce an entangled state from any element of...
the underlying computational basis.

It can be given the type \( B \otimes B \rightarrow B \otimes B \) in the empty context. The following is a type derivation \( \pi_{EPR} \) for it:

\[
\frac{\cdot \vdash H : B \rightarrow B \quad \cdot \vdash x : B}{\cdot \vdash x : B \quad \vdash H x : B} (E_\rightarrow)
\]

\[
\frac{\cdot \vdash CNOT : B \otimes B \rightarrow B \otimes B}{\cdot \vdash x : B, y : B \vdash CNOT(H x \otimes y) : B \otimes B} (E_\otimes)
\]

\[
\frac{\cdot \vdash \pi_{EPR} : B \otimes B \rightarrow B \otimes B}{\cdot \vdash \pi_{EPR}(H x) : B \otimes B} (E_\otimes)
\]

\( M_{EPR} \) and \( \pi_{EPR} \) will be used as running examples in the rest of this paper, together with the following type derivation \( \rho_{EPR} \):

\[
\frac{\cdot \vdash |0\rangle_1 : B \quad \cdot \vdash |1\rangle_2 : B}{\cdot \vdash \pi_{EPR} \cdot \vdash M_{EPR} : B \otimes B \rightarrow B \otimes B \quad \cdot \vdash \rho_{EPR}(|0\rangle_1 |1\rangle_2) : B \otimes B} (E_\otimes)
\]

If \( \pi \triangleright \Gamma \vdash (\lambda x.M)N : A \), one can build a type derivation \( \rho \) with conclusion \( \Gamma \vdash M\{x/N\} : A \) in a canonical way, and similarly when \( \pi \triangleright \Gamma \vdash (\lambda \langle x,y \rangle.M)(N \otimes L) : A \). This, as expected, is a consequence of the following:

**Lemma 1 (Substitution Lemma)** If \( \pi \triangleright \Gamma, x_1 : A_1, \ldots, x_n : A_n \vdash M : B \) and for every \( 1 \leq i \leq n \) there is \( \rho_i \triangleright \Delta_i \vdash N_i : A_i \), then there is a canonically defined derivation \( \pi\{x_1, \ldots, x_n/\rho_1, \ldots, \rho_n\} \) of \( \Gamma, \Delta_1, \ldots, \Delta_n \vdash M\{x_1, \ldots, x_n/N_1, \ldots, N_n\} : B \).

**Proof.** Just proceed by the usual, simple induction on \( \pi \). \( \square \)

### 2.3 An Equational Theory.

The \( \lambda \)-calculus is usually endowed with notions of reduction or equality, both centred around the \( \beta \)-rule, according to which a function \( \lambda x.M \) applied to an argument \( N \) reduces to (or can be considered equal to) the term \( M\{N/x\} \) obtained by replacing all free occurrences of \( x \) with \( N \). A reduction relation implicitly provides the underlying calculus with a notion of computation, while an equational theory is more akin to a reasoning technique. Giving a reduction relation on \( QA \) terms directly, however, is problematic. What happens when a \( n \)-ary unitary operator \( U \) is faced with an \( n \)-tuple of qubits \( |b_1 \ldots b_n\rangle \)? Superposition should somehow arise, but how can we capture it?

In this section, an equational theory for \( QA \) will be introduced. In the next sections, we will show that the semantics induced by token machines is *sound* with respect to it. The equational theory we are going to introduce will be a binary relation on formal, weighted sums of \( QA \) terms:

**Definition 1 (Superposed Term)** A superposed term of type \((\Gamma, A)\) is a formal sum

\[
\mathcal{F} = \sum_{i=1}^{n} x_i M_i
\]

---

\( ^1 \) The quantum circuit EPR is built out from the unitary gates \( H \) (the so-called Hadamard gate) and \( CNOT \). The unary gate \( H \) is able to create a superposition of elements of the computational basis \(|0\rangle \) and \(|1\rangle \), i.e. a linear combination in the form \( \frac{1}{\sqrt{2}}(|0\rangle + |1\rangle) \) or \( \frac{1}{\sqrt{2}}(|0\rangle - |1\rangle) \). The binary gate \( CNOT \) negates its second argument, according to the value of the first one. We provide two simple examples of entangled and non-entangled quantum states. The state \( |\psi\rangle = \frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle \) is entangled whereas any state \( \phi = \alpha|00\rangle + \beta|11\rangle \) is not. In fact, it is possible to express the latter in the mathematically equivalent form \( \phi = |0\rangle \otimes (\alpha|0\rangle + \beta|1\rangle) \). See [8] for a gentle introduction to quantum computing essential notions.
where for every $1 \leq i \leq n$, $\kappa_i \in \mathbb{C}$ and there is $\pi_i$ such that $\pi_i \vdash \Gamma \vdash M_i : A$. In this case, we write $\Gamma \vdash \mathcal{T} : A$.

Superposed terms will be denoted by metavariables like $\mathcal{T}$ or $\mathcal{S}$. Please observe that terms in a superposed term are uniformly typed, i.e., they can be given the same type in the same context. Please, notice that:

- If $\pi \vdash \cdot \vdash U|b_1 \ldots b_k : \mathbb{B}^k$, then there is a naturally defined superposed term of type $(\cdot, \mathbb{B}^k)$ which is nothing more than the element of $\mathbb{C}^{2^k}$ obtained by applying $U$ to the vector $|b_1 \ldots b_k\rangle$. With a slight abuse of notation, this superposed term will be indicated with $U|b_1 \ldots b_k\rangle$.
- All the term constructs can be generalised to operators on superposed terms, with the proviso that the types match. As an example if $\mathcal{T} = \sum_i \alpha_i M_i$ where $\pi_i \vdash \Gamma \vdash M_i : A \rightarrow B$ and $\rho \vdash \Delta \vdash N : A$, then $\mathcal{T}N$ denotes the superposed term $\mathcal{S} = \sum_i \alpha_i(M_iN)$. Indeed, there exist type derivations $\sigma_i \vdash \Gamma, \Delta \vdash M_iN : B$ each obtained applying the rule (E$_\rightarrow$) to $\pi_i$ and $\rho$.

It is now time to define our equational theory, which will be defined on superposed terms of the same type. Formally, $\approx$ is a binary relation on superposed terms, indexed by contexts and types. The fact that $\mathcal{T} \approx_{\Gamma, A} \mathcal{S}$ is indicated with $\Gamma \vdash \mathcal{T} \approx \mathcal{S} : A$. The relation $\approx$ is defined inductively, by the rules in Figure 2. Notice that for each $\Gamma, A, \approx_{\Gamma, A}$ is by construction an equivalence relation.

**Example 2** As an example, consider the term $M_{EPR}(|0\rangle \otimes |1\rangle_2)$ from Example 1. The equations in the following chain can all be derived through axioms and context closure rules:

$$M_{EPR}(|0\rangle \otimes |1\rangle) \approx CNOT(H|0\rangle \otimes |1\rangle) \approx \frac{1}{\sqrt{2}}CNOT(|0\rangle \otimes |1\rangle) + \frac{1}{\sqrt{2}}CNOT(|1\rangle \otimes |1\rangle)$$

$$\approx \frac{1}{\sqrt{2}}|0\rangle \otimes |1\rangle + \frac{1}{\sqrt{2}}CNOT(|1\rangle \otimes |1\rangle) \approx \frac{1}{\sqrt{2}}|0\rangle \otimes |1\rangle + \frac{1}{\sqrt{2}}|1\rangle \otimes |0\rangle.$$

The context (which is $\cdot$) and the type (which is $\mathbb{B}^2$) have been elided for the sake of readability. By rule trans, we can derive that

$$\vdash EPR(|0\rangle \otimes |1\rangle) \approx \frac{1}{\sqrt{2}}|0\rangle \otimes |1\rangle + \frac{1}{\sqrt{2}}|1\rangle \otimes |0\rangle : \mathbb{B}^2.$$

In other words, EPR, when fed with $|0\rangle \otimes |1\rangle$, produces an entangled pair of qubits. The fourth superposed term in the chain above has the remarkable property of not being homogeneous, i.e., of being the sum of two terms which are not identical up to the value of bit constants.

Please observe that the equational theory we have just defined can hardly be seen as an operational semantics for QA. Although equations can of course be oriented, it is the very nature of a superposed term which is in principle problematic from the point of view of quantum computation: what is the mathematical nature of a superposed term? Is it an element of an Hilbert space? And if so, of which one? If we consider a simple language such as QA, the questions above may appear overly rhetorical, but we claim they are not. For example, what would be the quantum meaning of linear beta-reduction? If we want to design beta-reduction according to the principles of quantum computation, it has to be, at least, easily reversible (unless measurement is implicit in it). Moving towards more expressive languages, this non-trivial issue becomes more difficult and a number of constraints have to be imposed (for example, superposition of terms can be allowed, but only between homogenous terms [19]). This is the reason for which promising calculi [19] fail to be canonical models for quantum programming languages. This issue has been faced in literature without satisfactory answers, yielding a number of convincing arguments in favour of the (implicit or explicit) classical control of quantum data [5, 16]. As observed above, our equational theory permits non-homogeneous superposed terms in a very natural way.
### Axioms

\[
\begin{align*}
\Gamma \vdash (\lambda \langle x, y \rangle. M)(N \otimes L) : A & \quad \text{beta.pair} \\
\Gamma \vdash (\lambda \langle x, y \rangle. M)(N \otimes L) \approx M\{x/N, y/L\} : A \\
\Gamma \vdash (\lambda x. M) N : A & \quad \text{beta} \\
\Gamma \vdash (\lambda x. M) N \approx M\{x/N\} : A \\
\vdash U|b_1 \ldots b_k : B^k & \quad \text{quant} \\
\vdash U|b_1 \ldots b_k \approx U|b_1 \ldots b_k : B^k
\end{align*}
\]

### Context Closure

\[
\begin{align*}
\Gamma, \Delta \vdash T \approx S : A \rightarrow B & \quad \text{l.a} \\
\Delta \vdash M : A & \quad \Delta \vdash \mathcal{I} \approx \mathcal{I} : A \\
\Gamma, \Delta \vdash \mathcal{I} M \approx \mathcal{I} M : B & \quad \Gamma, \Delta \vdash \mathcal{I} \approx \mathcal{I} : A \\
\Gamma, x : A, y : B \vdash \mathcal{I} \approx \mathcal{I} : C & \quad \mathcal{I}, \lambda \vdash \mathcal{I} \approx \mathcal{I} : A \\
\Gamma \vdash \lambda (x, y). \mathcal{I} \approx \lambda (x, y). \mathcal{I} : A \otimes B \rightarrow C & \quad \Gamma \vdash \lambda \mathcal{I} \approx \lambda \mathcal{I} : A \rightarrow B \\
\Gamma \vdash M : A & \quad \Delta \vdash \mathcal{I} \approx \mathcal{I} : B \\
\Delta \vdash \mathcal{I} \approx \mathcal{I} : B & \quad \Gamma, \Delta \vdash \mathcal{I} \otimes M \approx \mathcal{I} \otimes M : A \otimes B \\
\Gamma, \Delta \vdash M \otimes \mathcal{I} \approx M \otimes \mathcal{I} : A \otimes B & \quad \Gamma \vdash \mathcal{I} \approx \mathcal{I} : A \\
\Gamma, \Delta \vdash \mathcal{I} \approx \mathcal{I} : B & \quad \Gamma \vdash \mathcal{I} \approx \mathcal{I} : A \\
\Gamma \vdash \alpha \mathcal{I} + \mathcal{I} \approx \alpha \mathcal{I} + \mathcal{I} : A & \quad \mathcal{I}, \Delta \vdash \mathcal{I} \approx \mathcal{I} : A \\
\end{align*}
\]

### Reflexive, Symmetric and Transitive Closure

\[
\begin{align*}
\Gamma \vdash \mathcal{I} : A & \quad \text{refl} \\
\Gamma \vdash \mathcal{I} \approx \mathcal{I} : A & \quad \text{sym} \\
\Gamma \vdash \mathcal{I} \approx \mathcal{I} : A & \quad \text{trans}
\end{align*}
\]

**Figure 2: Equational Theory**
3 A Token Machine for QA

In this section we describe an interpretation of QA type derivations in terms of a specific token machine called IAMQA. Before formally defining IAMQA, it is necessary to give some preliminary concepts.

With a slight abuse of notation, a permutation \( \sigma : \{1, \ldots, n\} \to \{1, \ldots, n\} \) will be often applied to sequences of length \( n \) with the obvious meaning: \( \sigma(a_1, \ldots, a_n) = a_{\sigma(1)}, \ldots, a_{\sigma(n)} \). Similarly, such a permutation can be seen as the unique unitary operator on \( \mathbb{C}^{2^n} \) which sends \( |b_1 \cdots b_n\rangle \) to \( |b_{\sigma(1)} \cdots b_{\sigma(n)}\rangle \).

Suppose given a unitary operator \( U \in \mathcal{U} \) of arity \( n \in \mathbb{N} \). Now, take a natural number \( m \geq n \) and \( n \) distinct natural numbers \( j_1, \ldots, j_n \), all of them smaller or equal to \( m \). With \( U_{j_1 \cdots j_n} \) (or simply with \( U_{j_1 \cdots j_n} \)) we indicate the unitary operator of arity \( m \) which acts like \( U \) on the quantum bits indexed with \( j_1, \ldots, j_n \) and leave all the other qubits unchanged. In the following, with a slight abuse of notation, occurrences of types in type derivations are confused with types themselves. On the other hand, occurrences of types inside other types will be defined quite precisely, as follows.

Contexts (types with a hole) are denoted by metavariables like \( C \) or \( D \). A context \( C \) is said to be a context for a type \( A \) if \( C[B] = A \). Negative contexts (i.e., contexts where the hole is in negative position) are denoted by metavariables like \( N, M \). Positive ones are denoted by metavariables like \( P, Q \). An occurrence of \( B \) in the type derivation \( \pi \) is a pair \( \phi = (A, C) \), where \( A \) is an occurrence of a type in \( \pi \) and \( C \) is a context for \( A \). Sequences of occurrences are indicated with metavariables like \( \varphi, \psi \) (possibly indexed). All sequences of occurrences we will deal with do not contain duplicates. Type constructors \( \rightarrow \) and \( \otimes \) can be generalised to operators on occurrences and sequences of occurrences, e.g. \( (A, C) \rightarrow B \) is just \( (A \rightarrow B, C \rightarrow B) \). If a sequence of occurrences \( \varphi \) contains the occurrences \( O_1, \ldots, O_n \), we emphasise it by indicating it with \( \varphi(O_1, \ldots, O_n) \).

Given (an occurrence of) a type \( A \), all positive and negative occurrences of \( B \) inside \( A \) form sequences called \( \mathcal{P}(A) \) and \( \mathcal{N}(A) \), respectively. These are defined as follows (where \( \cdot \) is sequence concatenation):

\[
\begin{align*}
\mathcal{P}(B) &= (B, [\cdot]); \\
\mathcal{N}(B) &= \varepsilon; \\
\mathcal{P}(A \otimes B) &= (\mathcal{P}(A) \otimes B) \cdot (A \otimes \mathcal{P}(B)); \\
\mathcal{N}(A \otimes B) &= (\mathcal{N}(A) \otimes B) \cdot (A \otimes \mathcal{N}(B)); \\
\mathcal{P}(A \rightarrow B) &= (\mathcal{N}(A) \rightarrow B) \cdot (A \rightarrow \mathcal{P}(B)); \\
\mathcal{N}(A \rightarrow B) &= (\mathcal{P}(A) \rightarrow B) \cdot (A \rightarrow \mathcal{N}(B)).
\end{align*}
\]

Example 3 As an example, the positive occurrences in the type \( B \rightarrow B \otimes B \) should be the two rightmost ones. And, indeed,

\[
\begin{align*}
\mathcal{P}(B \rightarrow B \otimes B) &= (\mathcal{N}(B) \rightarrow B \otimes B) \cdot (B \rightarrow \mathcal{P}(B \otimes B)) \\
&= \varepsilon \cdot (B \rightarrow \mathcal{P}(B \otimes B)) \\
&= B \rightarrow \mathcal{P}(B \otimes B) \\
&= (B \rightarrow (\mathcal{P}(B) \otimes B)) \cdot (B \rightarrow (B \otimes \mathcal{P}(B))) \\
&= (B, B \rightarrow (\cdot \otimes B)) \cdot (B, B \rightarrow (B \otimes [\cdot])).
\end{align*}
\]

Similarly, one can prove that \( \mathcal{N}(B \rightarrow B \otimes B) = (B, [\cdot] \rightarrow (B \otimes B)) \).

For every type derivation \( \pi \), \( \mathcal{B}(\pi) \) is the sequence of all these occurrences of \( B \) in \( \pi \) which are introduced by the rules (a\(_{q0}\)) and (a\(_{q1}\)) (recall Figure 1). Similarly, \( \mathcal{V}(\pi) \) is the corresponding sequence of binary
digits, seen as a vector in $\mathbb{C}^{2^{|\mathcal{D}(\pi)|}}$. Both in $\mathcal{A}(\pi)$ and in $\mathcal{V}(\pi)$, the order is the one induced by the natural number labeling the underlying bit in $\pi$.

**Example 4** Consider the following type derivation, and call it $\tau$:

$$
\vdash |0\rangle_2 : B_1 \quad \vdash |1\rangle_1 : B_2
\vdash |0\rangle_2 \otimes |1\rangle_1 : B_3 \otimes B_4 \quad (I_\otimes)
$$

There are four occurrences of $B$ in it, and we have indexed it with the first four positive natural numbers, just to be able to point at them without being forced to use the formal, context machinery. Only two of them, namely the upper ones, are introduced by instances of the rules $(a_{q0})$ and $(a_{q1})$. Moreover, the rightmost one serves to type a bit having an index (namely 1) greater than the one in the other instance (namely 2). As a consequence, $\mathcal{A}(\tau)$ is the sequence $B_2, B_1$. The two instances introduces bits 0 and 1; then $\mathcal{V}(\pi) = |1\rangle \otimes |0\rangle$. As another example, one can easily compute $\mathcal{A}(\pi_{EPR})$ and $\mathcal{V}(\pi_{EPR})$ (where $\pi_{EPR}$ is from Example [7]), finding out that both are the empty sequence.

We are finally able to define, for every type derivation $\pi$, the abstract machine $\mathcal{A}_\pi$ interpreting it:

- The types of $\mathcal{A}_\pi$ form a set $\mathcal{T}_\pi$ and are in the form $S = (O_1, \ldots, O_n, Q)$ where:
  - $O_1, \ldots, O_n$ are occurrences of the type $B$ in $\pi$;
  - $Q$ is a quantum register on $n$ quantum bits, i.e. a normalised vector in $\mathbb{C}^2^n$.
- The transition relation $\mathcal{T} \subseteq \mathcal{A}_\pi \times \mathcal{T}_\pi$ is defined based on $\pi$, following the rules from Figure [3]. In the last rule, $B$ in the type of $U$ is simply denoted through its index, and for every $1 \leq k \leq m$, $i_k$ is the position of $B_k$ in the sequence $\varphi$. The transition rules induced by $([I_\omega])$ have been elided for the sake of simplicity (see [8]).

The number of positive (negative, respectively) occurrences of $B$ in the conclusion of $\pi$ is said to be the output arity (the input arity, respectively) of $\pi$. Suppose, for the sake of simplicity, that $\pi$ is a type derivation of $\vdash M : A$. An initial state for a quantum register $Q$ is a state in the form $(\mathcal{N}(A) \cdot \mathcal{A}(\pi), Q \otimes \mathcal{V}(\pi))$. Given a permutation $\sigma$ on $n$ elements, a final state for a quantum register $Q$ and $\sigma$ is a state in the form $(\varphi, Q)$, where $\varphi = \sigma(\mathcal{P}(A))$. A run of $\mathcal{A}_\pi$ is simply a finite or infinite sequence $S_1, S_2, \ldots$ of states from $\mathcal{T}_\pi$ such that $S_i \rightarrow S_{i+1}$ for every $i$.

**Example 5 (A run of IAMQX)** Consider the term $M_{EPR}$ and its type derivation $\pi_{EPR}$ (see Example [7]). Forgetting about terms and marking different occurrences of $B$ with distinct indices, we obtain:

$$
\vdash B_1 \rightarrow B_2, B_2 \vdash B_3 \rightarrow B_4 \quad (E_{\omega})
\vdash B_9 \otimes B_{10} \rightarrow B_{11} \otimes B_{12} \quad (I_\omega)
\vdash B_5 \rightarrow B_6, B_6 \vdash B_7 \rightarrow B_8 \quad (E_{\omega})
\vdash B_1 \rightarrow B_2, B_2 \rightarrow B_3 \otimes B_4 \quad (I_\omega)
$$

Let us consider the following computation of $\mathcal{A}_{\pi_{EPR}}$:

$$
(B_1, B_2, Q) \rightarrow^* \pi (B_5, B_6, Q) \rightarrow^* \pi (B_{13}, B_{14}, Q) \rightarrow^* \pi (B_{17}, B_{19}, Q) \rightarrow^* \pi (B_{23}, B_{20}, Q)
\rightarrow^* \pi (B_{24}, B_{16}) \rightarrow^* \pi (B_{24}, B_{10}, Q) \rightarrow^* \pi (B_{21}, B_{10}, Q) \rightarrow^* \pi (B_{22}, B_{10}, H^1(Q))
\rightarrow^* \pi (B_{18}, B_{10}, H^1(Q)) \rightarrow^* \pi (B_{15}, B_{10}, H^1(Q)) \rightarrow^* \pi (B_{9}, B_{10}, H^1(Q))
\rightarrow^* \pi (B_{11}, B_{12}, CNOT^{1,2}(H^1(Q))) \rightarrow^* \pi (B_{7}, B_{8}, CNOT^{1,2}(H^1(Q)))
\rightarrow^* \pi (B_{3}, B_{4}, CNOT^{1,2}(H^1(Q))).
$$
Figure 3: IAMQA Transition Rules
Notice that the occurrence of $\text{CNOT}$ acts as a synchronisation operator: the second token is stuck at the occurrence $B_{10}$ until the first token arrives (from the occurrence $B_{15}$) as a control input of the CNOT and the corresponding reduction step actually occurs.

What the example above shows, indeed, is that the presence of a potential entanglement in $\pi$ is intimately related to the necessity of synchronisation in the underlying machine $\mathcal{A}_\pi$: if all unitary operators in $\pi$ can be expressed as the tensor product of unitary operators of arity one (and, thus, entanglement is not possible), then synchronisation is simply not necessary.

Given a type derivation $\pi$, the relation $\to_\pi$ enjoys a strong form of confluence:

**Proposition 1 (One-step Confluence of $\to_\pi$)** Let $S, R, T \in \mathcal{S}_\pi$ be such that $S \to_\pi R$ and $S \to_\pi T$. Then either $R = T$ or there exists a state $U$ such that $R \to_\pi U$ and $T \to_\pi U$.

**Proof.** By simply inspecting the various rules. Notice that there are no critical pairs in $\to_\pi$. $\square$

The way $\mathcal{A}_\pi$ is built by following a type derivation $\pi$ induces the following notion:

**Definition 2** Given a type derivation $\pi$, the partial function computed by $\pi$ is denoted as $[\pi]$, has domain $\mathbb{C}^{2^n}$ and codomain $\mathbb{C}^{2^m}$ (where $n$ and $m$ are the input and output arity of $\pi$) and is defined by stipulating that $[\pi](Q) = R$ iff any initial state for $Q$ rewrites into a final state for $S$ and $\sigma$, where $S = \sigma^{-1}(R)$.

Given a type derivation $\pi$, $[\pi]$ is either always undefined or always defined. Indeed, the fact any initial configuration (for, say, $Q$) rewrites to a final configuration or not does not depend on $Q$ but only on $\pi$:

**Lemma 2 (Uniformity)** For every type derivation $\pi$ and for every occurrences $O_1, \ldots, O_n, P_1, \ldots, P_n$, there is a unitary operator $U$ such that whenever $(O_1, \ldots, O_n, Q) \to_\pi (P_1, \ldots, P_n, R)$ it holds that $R = U(Q)$.

**Proof.** Observe that for every $O_1, \ldots, O_n, P_1, \ldots, P_n$ there is at most one of the rules defining $\to_\pi$ which can be applied. Moreover, notice that each rule acts uniformly on the underlying quantum register. $\square$

In the following section, we will prove that $[\pi]$ is always a total function, and that it makes perfect sense from a quantum point of view.

## 4 Main Properties of $\text{IAM}_{\text{QA}}$

In this section, we will give some crucial results about $\text{IAM}_{\text{QA}}$. More specifically, we prove that runs of this token machine are indeed finite and end in final states. We proceed by putting QA in correspondence to MLL, inheriting its very elegant proof theory and token machines.

### 4.1 A Correspondence Between MLL and QA

Let $\mathbb{A} = \{\alpha, \beta, \ldots\}$ be a countable set of propositional atoms. A formula $A$ of Multiplicative Linear Logic (MLL) is given by the following grammar:

$$A, B ::= \alpha \mid \alpha^\perp \mid A \otimes B \mid A \oslash B.$$

Linear negation can be extended to all formulas in the usual way:

$$(\alpha^\perp)^\perp = \alpha; \quad A \otimes B^\perp = A^\perp \oslash B; \quad A \oslash B^\perp = A^\perp \otimes B.$$
This way, $A^\bot\bot$ is just $A$. The one-sided sequent calculus for MLL is very simple:

\[
\frac{}{\Gamma, A \vdash A, A^\bot} \text{ax} \quad \frac{\Gamma, A \vdash \Delta, A^\bot}{\vdash \Gamma, \Delta} \text{cut} \quad \frac{\Gamma, A \vdash \Delta, B}{\vdash \Gamma, \Delta, A \otimes B} \quad \frac{\Gamma, A \vdash \gamma}{\vdash \Gamma, A \gamma B}
\]

The logic MLL enjoys cut-elimination: there is a terminating algorithm turning any MLL proof into a cut-free proof of the same conclusion. A notion of structural equivalence between two MLL proofs $\xi, \mu$ having the same conclusion $\vdash \Gamma$ can be easily defined and holds only if $\xi$ and $\mu$ are essentially the same proof modulo renaming of the formulas occurring in $\xi$ and $\mu$. Remarkably, two MLL proofs which are structurally equivalent are actually the same proof, a result which does not hold in more expressive logics like MELL. More details on that can be found in [8].

Any QA type derivation $\pi$ can be put in correspondence with some MLL proofs. We inductively define the map $(\cdot)^*$ from QA types to MLL formulas as follows:

\[
(\mathbb{B})^* = \alpha; \quad (A \rightarrow B)^* = (A)^\bot \gamma (B)^*; \quad (A \otimes B)^* = (A)^* \otimes (B)^*
\]

Given a judgment $J = \Gamma \vdash M : A$ and a natural number $n \in \mathbb{N}$, the MLL sequent corresponding to $J$ and $n$ is the following one:

\[
\vdash \alpha^\perp, \ldots, \alpha^\perp, ((B_1)^*)^\perp, \ldots, ((B_m)^*)^\perp, (A)^*, \text{ n times}
\]

where $\Gamma = x_1 : B_1, \ldots, x_m : B_m$. For every $\pi$, we define now a set of MLL proofs $\mathcal{J}(\pi)$. This way, every type derivation $\pi$ for $J = \Gamma \vdash M : A$ such that $n$ bits occur in $M$, is put in relation to possibly many MLL proofs of the sequent corresponding to $J$ and $n$. One among them is called the canonical proof for $\pi$. The set $\mathcal{J}(\pi)$ and canonical proofs are defined by induction on the structure of the underlying type derivation $\pi$. The type constructions of QA are mapped to the corresponding MLL logical operators, rules $(a_{q0})$ and $(a_{q1})$ are mapped to axioms, and rule $(a_{u})$ is mapped to a proof encoding a permutation of the involved atoms. When the latter is the identity, we get the canonical proof for $\pi$. For more details, please refer to [8].

Given an MLL proof $\xi$, let us denote as $T_\xi$ the class of all finite sequences of atom occurrences in $\xi$. The relation $\rightarrow^\perp_\xi$ can be extended to a relation on $T_\xi$ by stipulating that

\[
(O_1, \ldots, O_{n-1}, P, O_{n+1}, \ldots, O_m) \rightarrow^\perp_\xi (O_1, \ldots, O_{n-1}, R, O_{n+1}, \ldots, O_m)
\]

whenever $P \rightarrow^\perp_R$. As usual, $\rightarrow^+_\xi$ is the transitive closure of $\rightarrow^\perp_\xi$.

Let us now consider a type derivation $\pi$ in QA, its quantum token machine $\mathcal{A}_\pi$, and any $\xi \in \mathcal{J}(\pi)$. States of $\mathcal{A}_\pi$ can be mapped to $T_\xi$ by simply forgetting the underlying quantum register and mapping any occurrence of $\pi$ to the corresponding atom occurrence in $\xi$. This way one gets a map

\[
\mathcal{R}_{\pi, \xi} : \mathcal{J}(\pi) \rightarrow T_\xi
\]

such that, given a state $S = (O_1, \ldots, O_n, Q)$ in $\mathcal{J}(\pi)$, $|\mathcal{R}_{\pi, \xi}(S)| = n$, i.e., the number of occurrences in $S$ is the same as the length of $\mathcal{R}_{\pi, \xi}(S)$. Each reduction step on the token machine $\mathcal{A}_\pi$ corresponds to at least one reduction step in the MLL machine $\mathcal{M}_\xi$, where $\xi \in \mathcal{J}(\pi)$ is the canonical proof:

**Lemma 3** Let us consider a token machine $\mathcal{A}_\pi$ and two states $S, R \in \mathcal{J}(\pi)$. If $S \rightarrow^\perp_\xi R$ and $\xi \in \mathcal{J}(\pi)$ is canonical, then $\mathcal{R}_{\pi, \xi}(S) \rightarrow^+_\xi \mathcal{R}_{\pi, \xi}(R)$.

**Proof.** This goes by induction on the structure of $\pi$. □

Any (possible) pathological situation on the quantum token machine, then, can be brought back to a corresponding (absurd) pathological situation in the MLL token machine. This is the principle that will guide us in the rest of this section.
4.2 Termination, Progress and Soundness

The first property we want to be sure about is that every computation of any token machine $A_\pi$ always terminates. The second one is progress (i.e. deadlock-freedom). In both cases, we use in an essential way the correspondence between QA and MLL.

Proposition 2 (Termination) For any quantum token machine $A_\pi$, any sequence $S \rightarrow_\pi R \rightarrow_\pi \ldots$ is finite.

Proof. Suppose, for the sake of contradiction, that there exists an infinite computation in $A_\pi$. This implies by Lemma 3 that there exists an infinite path in the token machine $M_\xi$ where $\xi$ is the canonical MLL proof for $\pi$. This is a contradiction, because paths in MLL proofs are well-known to be always finite. □

Progress (i.e. deadlock-freedom) is more difficult to prove than termination. Given a type derivation $\pi$, an argument occurrence is any negative occurrence $(A,N)$ of $B$ in a $(a_\cup)$ axiom. We extend this definition to the corresponding atom occurrence when $\xi \in J(\pi)$. A result occurrence is defined similarly, but the occurrence has to be positive.

Proposition 3 (Progress) Suppose $\pi$ is a type derivation in QA and $S \in J_\pi$ is initial. Moreover, suppose that $S \rightarrow_\pi R$. Then either $R$ is final or $R \rightarrow_\pi T$ for some $T \in J_\pi$.

Proof. Let us consider a computation $S_1 \rightarrow_\pi \ldots \rightarrow_\pi S_k$ on a quantum token machine $A_\pi$. Suppose that the state $S_k$ is a deadlocked state, i.e. $S_k$ is not a final state, and that there exists no $S_m$ such that $S_k \rightarrow_\pi S_m$. The fact $S_k$ is a deadlocked state means that $l \geq 1$ occurrences in $S_k$ are argument occurrences, since the latter are the only points of synchronisation of the machine. Let us consider any maximal sequence

$$A_\pi, \xi(S_1) \rightarrow_\xi \ldots \rightarrow_\xi A_\pi, \xi(S_k) \rightarrow_\xi Q_1 \rightarrow_\xi \ldots \rightarrow_\xi Q_n,$$

where $\xi \in J(\pi)$ is the canonical proof corresponding to $\pi$. Observe that in (1), all occurrences of atoms in $\xi$ are visited exactly once, including those corresponding to argument and result occurrences from $\pi$. Notice, however, that the argument and result occurrences of the unitary operators affected by $S_k$ cannot have been visited along the subsequence $A_\pi, \xi(S_1) \rightarrow_\xi \ldots \rightarrow_\xi A_\pi, \xi(S_k)$ (otherwise we would visit the occurrences in $S_k$ at least twice, which is not possible). Now, form a directed graph whose nodes are the unitary constants $U_1, \ldots, U_h$ which block $S_k$, plus a node $F$ (representing the conclusion of $\pi$), and whose edges are defined as follows:

- there is an edge from $U_i$ to $U_j$ iff along $Q_1 \rightarrow_\xi \ldots \rightarrow_\xi Q_n$ one of the $l$ independent computations corresponding to a blocked occurrence in $S_k$ is such that a result occurrence of $U_i$ is followed by an argument occurrence of $U_j$ and the occurrences between them are neither argument nor result occurrences.
- there is an edge from $U_i$ to $F$ iff along $Q_1 \rightarrow_\xi \ldots \rightarrow_\xi Q_n$ one of the $l$ traces is such that a result occurrence of $U_i$ is followed by a final occurrence of an atom and the occurrences between them are neither argument nor result occurrences.

The thus obtained graph has the following properties:

- Every node $U_i$ has at least one incoming edge, because otherwise the configuration $S_k$ would not be deadlocked.
- As a consequence, the graph must be cyclic, because otherwise we could topologically sort it and get a node with no incoming edges (meaning that some of the $U_i$ would not be blocked!). Moreover, the cycle does not include $F$, because the latter only has incoming nodes.
From any cycle involving the $U_j$, one can induce the presence of a cycle in the token machine $\mathcal{M}_\mu$ for some $\mu \in \mathcal{I}(\pi)$. Indeed, such a $\mu$ can be formed by simply choosing, for each $U_j$, the “good” permutation, namely the one linking the incoming edge and the outgoing edge which are part of the cycle. This way, we have reached the absurd starting from the existence of a deadlocked computation. □

The immediate consequence of the termination and progress results is that $[\pi]$ is always a total function. The way $\mathcal{A}_\pi$ is defined ensures that $[\pi]$ is obtained by feeding some of the inputs of a unitary operator $U$ with some bits (namely those occurring in $\pi$). $U$ is itself obtained by composing the unitary operators occurring in $\pi$, which can thus be seen as a program computing a quantum circuit. In a way, then, token machines both show that QA is a truly quantum calculus and can be seen as the right operational semantics for it.

The last step consists in understanding the relation between token machines and the equational theory on superposed terms introduced in Section 2.3. First of all, observe that $\mathcal{T} = \sum_{i=1}^{n} \kappa_i M_i$ has type $A$ in the context $\Gamma$, then $M_1, \ldots, M_n$ all have type $A$ in the context $\Gamma$. But there is more to that: for every $1 \leq i \leq n$, there is exactly one type derivation $\pi_i : \Gamma \vdash M_i : A$. This holds because two such type derivations $\pi_i$ and $\rho_i$ are such that the canonical proofs in $\mathcal{I}(\pi_i)$ and $\mathcal{I}(\rho_i)$ are structurally equivalent, thus identical. It is then possible to extend the definition of $[\cdot]$ to superposed terms: if $\mathcal{T} = \sum_{i=1}^{n} \kappa_i M_i$ has type $A$ in $\Gamma$, then $[\mathcal{T}]$, when fed with a vector $x$, returns $\sum_{i=1}^{n} \kappa_i [\pi_i](x)$, where $\pi_i$ is the unique derivation giving type $A$ to $M_i$ in the context $\Gamma$. Remarkably, token machines behave in accordance to the equational theory: this is our Soundness Theorem.

**Theorem 1 (Soundness)** Given $\mathcal{T}$ and $\mathcal{I}$ superposed terms, if $\Gamma \vdash \mathcal{T} \approx \mathcal{I} : A$, then $[\mathcal{T}] = [\mathcal{I}]$.

**Proof.** We only give a sketch of the proof. More details can be found in [8]. The first step consists in proving that any derivation of $\Gamma \vdash \mathcal{T} \approx \mathcal{I} : A$ can be put in normal form, a concept defined by giving an order on the rules in Figure 2. More specifically, define the following two sets of rules:

$$AX = \{\text{beta}, \text{beta.pair}, \text{quant}\};$$

$$CC = \{l.a, r.a, in.\lambda, in.\lambda.pair, l.in.tens, r.in.tens\}.$$ A derivation of $\Gamma \vdash \mathcal{T} \approx \mathcal{I} : A$ is said to be in normal form (and we write $\Gamma \vdash \mathcal{T} \approx \mathcal{I} : A$) iff

- either the derivation is obtained by applying rule refl;
- or any branch in the derivation consists in instances of rules from $AX$, possibly followed by instances of rules in $CC$, possibly followed by instances of sum, possibly followed by instances of sym possibly followed by instances of trans.

In other words, a derivation of $\Gamma \vdash \mathcal{T} \approx \mathcal{I} : A$ is in normal form iff rules are applied in a certain order. As an example, we cannot apply transitivity or symmetry closure rules too early, i.e., before context closure rules. One may wonder whether this restricts the class of provable equivalences. Infact it does not: $\Gamma \Gamma \mathcal{T} \approx \mathcal{I} : A$ iff $\Gamma \Gamma \mathcal{T} \approx \mathcal{I} : A$, a result which is not particularly deep although a bit tedious to prove [8]. Once we have this result in our hands, however, proving Soundness becomes much easier, since the difficult and problematic rules, namely those in $CC$, are applied to superposed terms of a very specific shape, namely those obtained through $AX$. □

5 Related Work

In [13], a geometry of interaction model for Selinger and Valiron’s quantum $\lambda$-calculus [16] is defined. The model is formulated in particle-style. In [14], QMLL, an extension of MLL with a new kind of
modality, is studied. QMLL is sound and complete with respect to quantum circuits, and an interactive (particle-style) abstract machine is defined. In both cases, adopting a particle-style approach has a bad consequence: the “quantum” tensor product does not coincide with the tensor product in the sense of linear logic. Here we show that adopting the wave-style approach solves the problem. Quantum extensions of game semantics are partially connected to this work. See, for example [10, 9]. Purely linear quantum lambda-calculi (with measurements) can be given a fully abstract denotational semantics, like the one proposed by Selinger and Valiron [17]. In their work, closure (necessary to interpret higher-order functions) is not obtained via traces and is not directly related in any way to the geometry of interaction. Moreover, morphisms are just linear maps, and so the model is far from being a quantum operational semantics. A language of terms similar to QA has been also studied in [21], where the calculus of proof-nets MLL_{qm} is introduced. MLL_{qm}’s syntax also includes a measurement box-like operator (which models the possibility of “observe” the value of a quantum bit [15]). A multi-token machine semantics for MLL_{qm} proof-nets is defined and proved to be sound, i.e. invariant along reduction of proof nets. Moreover, although a \( \lambda \)-calculus is given, together with a compilation scheme to MLL_{qm} proof-nets, the considered \( \lambda \)-calculus is one with explicit qubits, contrary to QA. Finally, Arrighi and Dowek’s work shows that turning a sum-based algebraic \( \lambda \)-calculus into a quantum computational model can be highly non-trivial [1].

6 Conclusions

We have introduced IAM_{QA}, an interactive abstract machine which provides a sound operational characterisation of any type derivation in a linear quantum \( \lambda \)-calculus QA. This is an example of a concrete wave-style token machine whose runs cannot be seen simply as the asynchronous parallel composition of particle-style runs. Interestingly, synchronisation is intimately related to entanglement: if, for example, only unary operators occur in a term (i.e. entanglement is not possible), synchronisation is not needed and everything collapses to the particle-style. Our investigation is open to some possible future directions. A natural step will be to extend the syntax of terms and types with an exponential modality. The generalisation of the token machine to this more expressive language would be an interesting and technically challenging subject. Moreover, giving a formal status to the connection between wave-style and the presence of entanglement is a fascinating subject which we definitely aim to investigate further. Finally, an interesting proof-theoretical investigation would consist in analysing the possible connections the with the deep inference-oriented graph formalism developed in [3].
